Photoelectric dye used for Okayama University-type Retinal Prosthesis (OUReP™) reduces the apoptosis of photoreceptor cells

(光電変換色素の神経アポトーシス抑制効果)

[緒言] Introduction

Retinitis pigmentosa is a hereditary disease that involves the loss of retinal photoreceptor cells which perceive light. Patients with retinitis pigmentosa experience slowly progressive constriction of the visual field, caused by peripheral retinal dystrophy, and finally lose the vision by macular involvement. The speed of deterioration differs largely from patient to patient².

In blind patients with retinitis pigmentosa who have lost all photoreceptor cells, treatment strategy is to replace dead photoreceptor cells with retinal prosthesis. Several types of retinal prosthesis have been developed recently to replace the lost photoreceptor cells. The prevailing types of retinal prosthesis output electric current in correspondence to camera-captured and processed image, and stimulate the remaining retinal neurons which send axons to the brain. Other types of retinal prosthesis utilize photovoltaic systems⁷ or wireless subretinal neurostimulator⁸. Our system used photoelectric dye molecules to replace dead photoreceptor cells.

A photoelectric dye is an organic molecule which generates electric potential in response to light. Photoelectric dye-coupled polyethylene thin films (dye-coupled films), called Okayama University-type retinal prosthesis (OUReP™), induced neuronal response at light stimulation. Our previous studies showed that OUReP™ could reduce neuronal apoptosis in the eyes of Royal College of Surgeons (RCS) rats. In this study, we tested whether intravitreal injection of the photoelectric dye would rescue photoreceptor cells from the apoptosis in RCS rats.

[材料と方法] Materials and Methods

Animals and experimental design

Photoelectric dye molecules, 2-[2-[4-(dibutylamino) phenyl] ethenyl]-3-carboxymethylbenzothiazolium bromide (503.5 of molecular weight, NK-5962, Hayashibara, Inc., Okayama, Japan, Fig. 1A), were dissolved in distilled deionized water (Fig. 1B) at the concentration of 8.2 µg/ml (16 µM). This original stock solution (8.2 µg/ml) was diluted with saline (0.9% sodium chloride) to make a series of ten-fold dilutions from 8.2×10^{-4} µg/ml to 8.2 µg/ml. Twenty male pink-eyed RCS rats (RCS/Jcl-rdy/rdy, p-, CLEA Japan, Inc., Tokyo) at the age of 4 weeks were assigned to five groups (n=4) which received the dye at 5 different concentrations. Intravitreal injection was done twice at the age of 4 weeks and 5 weeks (Fig. 1D). This study was approved by the Animal Care and Use Committee at Okayama University, based on the Animal Welfare and Management Act in Japan. All experimental procedures were in accordance with the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research.

RCS rats were anesthetized by intraperitoneal injection of ketamine (87 mg/kg body weight) and xylazine (13 mg/kg). Mydriasis was induced by 0.5% tropicamide and 0.5% phenylephrine instillation, and corneal anesthesia was further obtained with 0.4% oxybuprocaine instillation. Under a dissecting microscope, 3 µl of dye solution and saline were injected into the vitreous of the left eye and the right eye, respectively, with a 30-gauge needle attached to a Hamilton syringe (50 µL 1705 LT SYR, Hamilton Company, Reno, NV, USA). The needle was inserted almost at a perpendicular angle, 1 mm from the corneoscleral limbus to avoid the damage to the lens. Next, antibiotic (0.5% moxifloxacin) eye drops were instilled to both eyes. Each rat was housed in a standard rat cage in the 12-hour-each light and dark cycle at the Animal Center of Okayama University. In a separate experiment, three rats were placed and maintained in constant darkness after intravitreal injection of the dye at the concentration of 8.2 µg/ml (16 µM).

Immunohistochemistry

At the age of 6 weeks, 2 weeks after the first injection, rats were sacrificed by an overdose of ether. The eyes were enucleated and fixed in 4% paraformaldehyde for 2 to 3 hours, cut into halves circumferentially in the midperiphery of the eye balls, and cryo-protected by immersion in 10% sucrose in 100 mM phosphate buffer (pH 7.4) for 3 hours. Serial frozen sections with 14 μm thickness were cut parallel to the vertical meridian of the eye at the optic nerve head, and immunohistochemical staining was done as described previously. The primary antibodies were anti-glial fibrillary acidic protein (GFAP) in 1:200 dilution (mouse monoclonal antibody, Chemicon, Temecula, CA, USA), and anti-protein kinase C α (PKC α) in 1:250 dilution (mouse monoclonal antibody, Sigma-Aldrich, St. Louis, MO, USA). Alexa Fluor 594 goat anti-mouse IgG was used as a fluorescence-conjugated secondary antibody. Nuclei were counterstained with 4',6-diamidino-2-phenylindole (DAPI). The tissue was covered with anti-fade reagents (ProLong Antifade Kit, Invitrogen, Waltham, MA, USA) and air-dried.

All images were captured at the constant exposure time with a frame (438 μm x 330 μm) by an Olympus FSX100 microscope, using 20x NA0.75 objective lens (Olympus, Tokyo, Japan), and saved as 24-bit RGB TIFF files. Alexa Fluor 594 and DAPI signals were sequentially detected with Olympus filter sets U-MWIG3 and U-MNUA2. GFAP or PKC α immunoreactivity was assessed in four retinal sites: "a" and "d", beginning at 373 μm superiorly and inferiorly from the optic nerve head, respectively, and sites "b" and "c", beginning at 160 μm superiorly and inferiorly from the optic nerve head, respectively (Fig. 1C). Five photographs in each of five retinal vertical sections per eye were taken, and an entire frame of each photograph with 20x objective lens was used for the following measurements.

RGB images were imported into the Image J software (National Institutes of Health, Bethesda, MD, USA), and converted to 8-bit grayscale images. For background subtraction, the mean background staining was defined by measuring an area positioned away from specific immunoreactive signals. After the background subtraction, the total area of immunoreactivity was determined by using a standardized histogram-based technique. To define a pixel as immunoreactive, constant threshold values were set to 50 for GFAP and 55 for PKC α immunoreactivity, respectively, and the number of pixels that matched or exceed each set threshold value was calculated for each image. Finally, the percentage of immunoreactive area was calculated from total immunoreactive area in a given size frame (height 193 μm , width 173 μm) at four predefined sites per retinal section (sites a, b, c, and d), and the data were compared by two-factor analysis of variance (ANOVA).

Apoptosis detection and retinal thickness measurement

Apoptotic cells were detected by terminal deoxynucleotidyl transferase-mediated fluorescein-conjugated-dUTP nick-end-labeling (TUNEL) assay, according to the manufacturer's instructions (In Situ Cell Death Detection Kit, Roche Diagnostics, Mannheim, Germany). The images at the constant exposure time were captured by an Olympus FSX100 microscope, equipped with the fluorescent filter cube U-MWIBA3. The areas for TUNEL assay were the same as those for immunohistochemical staining (sites a, b, c, and d). Five photographs in each of five retinal vertical sections per eye were taken, and an entire frame (220 μm x 165 μm) of each photograph with 40x NA0.95 objective lens was used for measurements. The number of TUNEL-positive cells in the inner nuclear layer and the outer nuclear layer was counted in each frame of photographs, and the thickness of the inner and outer nuclear layer was measured. The number of TUNEL-positive cells per 1,000 μm^2 of the inner nuclear layer or the outer nuclear layer was calculated for comparison by two-factor ANOVA.

[結果] Results

TUNEL staining and retinal thickness

TUNEL-positive signals were compared among the left eyes with dye injection at different concentrations and the right eyes with control saline injection. Under 12-hour light/dark cycle condition, in saline-injected eyes, numerous TUNEL-positive signals were detectable in the outer nuclear layer where the nuclei of photoreceptor cells were located. In contrast, TUNEL-positive cells appeared to decrease in all 4 different sites (a, b, c, and d) of retinal sections from dye-injected eyes (Fig. 2). TUNEL-positive cells in the outer nuclear layer were significantly different among different concentrations of the dye ($P=0.0001$), but not significantly different among 4 different retinal sites ($P=0.144$, two-factor ANOVA, Fig. 3). TUNEL-positive cells in the outer

nuclear layer of dye-injected eyes were significantly less at 3 higher concentrations of the dye, ranging from 16 μM to $16 \times 10^{-2} \mu\text{M}$, compared with saline-injected eyes ($P=0.0001$, $P=0.0001$, and $P=0.002$, post-hoc test, the least significant difference, Fig. 3).

In contrast, the number of TUNEL-positive cells in the inner nuclear layer was neither significantly different among different concentrations of the dye ($P=0.084$) nor among 4 different retinal sites ($P=0.927$, two-factor ANOVA, Fig. 4). However, post-hoc test showed significant decrease of the number of TUNEL-positive cells in the inner nuclear layer only at the highest concentration of the dye (16 μM), compared with saline ($P=0.043$, Fig. 4).

Morphometric analysis showed that the thickness of the outer nuclear layer was significantly different among different concentrations of the dye ($P=0.0001$) and among 4 different retinal sites ($P=0.014$, two-factor ANOVA, Fig. 5). The outer nuclear layer was significantly thicker in the dye-injected eyes at higher concentrations, ranging from 16 μM to $16 \times 10^{-2} \mu\text{M}$, compared with saline-injected eyes ($P=0.001$, $P=0.001$, and $P=0.026$, post-hoc test, Fig. 5), under 12-hour light/dark cycle condition. In addition, significant difference was noted in the thickness of the inner nuclear layer among different concentrations of the dye ($P=0.014$) and among 4 different retinal sites ($P=0.0001$, two-factor ANOVA, Fig. 6), under 12-hour light/dark cycle condition. However, post-hoc tests did not reach significance.

In another series of experiments, RCS rats injected with saline and dye at a highest concentration (16 μM) were kept under constant dark condition. The number of TUNEL-positive cells in the outer nuclear layer was significantly different between dye injection and saline injection ($P=0.0001$), but not significantly different among 4 different retinal sites ($P=0.982$, two-factor ANOVA). As post-hoc tests, the number of TUNEL-positive cells in the outer nuclear layer of the dye-injected eyes was significantly less than in the saline-injected eyes ($P=0.0001$), but no significant difference was noted in the number of TUNEL-positive cells between the constant dark condition and the 12-hour light/dark cycle ($P=0.411$, Fig. 2 and 3). The number of TUNEL-positive cells in the inner nuclear layer showed no significant difference between the dye-injected eyes and saline-injected eyes (Fig. 4).

Morphometric analysis showed that the outer nuclear layer tended to be thicker in the dye-injected eyes compared with saline-injected eyes under constant dark condition, although the difference was not significant ($P=0.054$, Fig. 5). No significant difference was noted in the thickness of the inner nuclear layer between the dye-injected and saline-injected eyes, under constant dark cycle condition ($P=0.145$, Fig. 6).

GFAP immunohistochemistry

GFAP-immunoreactive signals were compared among the left eyes with dye injection at different concentrations and the right eyes with control saline injection. In the saline-injected eyes, strong GFAP-immunoreactivity was present at Müller cells in all sites of the retina and was mainly localized on their end-feet which spread to the ganglion cell layer. In addition, radial Müller cell processes, running in the inner plexiform layer, showed intense GFAP-immunofluorescence (Fig. 7). In the dye-injected eyes, immunohistochemical localization of GFAP in the retina was basically similar to that observed in the saline-injected eyes (Fig. 7). At a closer look, many Müller cell radial processes, exhibiting weak and discontinuous staining, were noted in the inner plexiform layer (Fig. 7).

Semi-quantitative analysis showed that GFAP-immunoreactive areas were significantly different among different concentrations of the dye ($P=0.0001$) and also among 4 different retinal sites ($P=0.0001$, two-factor ANOVA, Fig. 8). GFAP-immunoreactive areas significantly decreased at two concentrations of the dye (16 μM and $16 \times 10^{-2} \mu\text{M}$) in the dye-injected eyes, compared with the saline-injected eyes ($P=0.023$ and $P=0.007$, post-hoc test, Fig. 8).

PKC α immunohistochemistry

In dye-injected eyes, PKC α immunoreactivity was evident in dendritic terminals of rod bipolar cells in the outer plexiform layer, somata in the inner nuclear layer, and axons, running perpendicularly throughout the inner plexiform layer, as well as the axon terminals located at the border between the inner plexiform layer and ganglion cell layer. The patterns of PKC α staining in the retina of the dye-injected eyes appeared to be different from those in the saline-injected eyes (Fig. 7). PKC α -immunoreactive areas were significantly different among different concentrations of the dye ($P=0.01$), but not significantly different among 4 different retinal sites ($P=0.413$, two-factor ANOVA, Fig. 9). Post-hoc tests showed significant increase of PKC α -immunoreactive areas at 3

higher dye concentrations, ranging from 16 μM to $16 \times 10^{-2} \mu\text{M}$, compared with saline injection ($P=0.002$, $P=0.003$, and $P=0.014$, respectively).

[考察] Discussion

The present study aimed to investigate whether the photoelectric dye has protective effect on retinal neurons. We used RCS rats as an animal model which show progressive photoreceptor degeneration as the consequence of a primary RPE gene mutation. Our results demonstrated that repeated intravitreal injection of the photoelectric dye provided the protection of the outer nuclear layer neurons at the earlier stage of dystrophy in RCS rats both under the 12-hour light/dark cycle and under the 24-hour continuous dark condition.

Many potential agents have been tested in animal models for their ability to protect photoreceptor cells from death. Ciliary neurotrophic factor (CNTF) has entered into a phase I clinical trial in human patients with retinitis pigmentosa²⁴. Our previous studies showed that the photoelectric dye-coupled films (OURePTM) could reduce neuronal apoptosis. In addition, the photoelectric dye could prevent retinal cells from death in mixed culture of glial cells and retinal neurons in vitro. We, therefore, speculated that the photoelectric dye might become a new neuroprotective agent.

Because the lens is relatively large in the small space of the eyeball of the rats, repeated intraocular injections would cause cataract formation and vitreous hemorrhage. We took care to reduce the incidence of cataract formation and vitreous hemorrhage after intravitreal injection. In the present study, the photoelectric dye was administered intravitreally twice at 4 weeks and 5 weeks of the age in RCS rats, and the rats were observed in the following 7 days. In the strain of RCS rats, used in this study, photoreceptor cells begin to degenerate on the 22th day after the birth, and the degeneration proceeds rapidly toward the 32th day. In a previous study, TUNEL-labeled photoreceptor cells suddenly appeared on 25 to 30 days, and the majority of the photoreceptor nuclei was TUNEL-labeled on 35 days of age. Few photoreceptor nuclei remain in the outer nuclear layer by the 60th day. We, therefore, chose the age of 4th week for the timing of injection to determine whether the photoelectric dye was effective to prevent photoreceptor cells from apoptotic death.

The treatment with the dye under 24-hour continuous dark condition also significantly reduced apoptotic cells. Furthermore, we found no difference in the number of retinal apoptotic cells between the 24-hour continuous dark condition and the 12-hour light/dark cycle. However, a previous study reported that dark condition could delay the deterioration of the dystrophic rat retina and that the animals in a dark environment showed less deterioration of the electroretinographic response. Further studies would be required to explain the contradictory results between the previous study and the present study, concerning the reduction of retinal apoptosis under constant dark and light/dark cycle condition.

GFAP is a constituent of glial filaments in astrocytes. In the central nervous system, astrocytes respond in an active manner when they suffer from diseases, trauma, chemical insults, and genetic disorders. Enhanced expression of GFAP is considered a marker of gliosis and hypertrophy of glial cells. Therefore, we examined GFAP immunoreactivity in retinal Müller cells after intravitreal dye injection. We found that intravitreal injection of the dye led to direct or indirect downregulation of GFAP expression, and might inhibit glial injury reaction. The variability in the semi-quantitative image analysis resulted in significant differences in GFAP-staining for some concentrations of the dye, but not for others. Nevertheless, the results suggest that photoelectric dye may downregulate GFAP expression and inhibit glial cell activation.

Rod bipolar cells are second-order retinal neurons that make synapses with rod photoreceptors, and their axon terminals are located in the inner plexiform layer, close to the ganglion cell layer. Because intraocular administration of the photoelectric dye showed inhibitory effect on photoreceptor cell apoptosis, we wondered whether intravitreal dye injection would also prevent rod bipolar cell dysfunction in RCS rats. Thus we performed immunohistochemical staining of PKC α , a rod bipolar cell marker. Dendrites of rod bipolar cells are the major phosphorylation sites of PKC α , and PKC α upregulation would indicate the improvement of bipolar cell function. Our data revealed that the atrophy of dendrites was correlated with decreased PKC α immunoreactivity in both dye-injected eyes and saline-injected control eyes. Furthermore, we observed significant increase of PKC α immunoreactivity in the eyes injected with higher concentrations of the dye. These data suggest that the photoelectric dye may help prevent rod bipolar cell dysfunction in RCS rats.

Previous studies by different groups showed that subretinal implantation of materials could slow down retinal degeneration. We initially considered that photoelectric dye-coupled polyethylene films in subretinal space of RCS rats' eyes would exert a similar protective effect on the retina, as described for other materials. The present study revealed that the photoelectric dye could slow down the process of retinal degeneration in RCS rats. The therapeutic effect of photoelectric dye on retinal protection, either dependent or independent of light, remains to be determined. Behavioral tests might help evaluate the efficacy of the dye in RCS rats, as performed previously in RCS rats with the dye-coupled film implantation.

A major limitation in this study is that we examined the apoptosis by TUNEL assay and the thinning of the outer nuclear layer in the ongoing process of retinal dystrophy at a rather earlier stage in RCS rats. Further studies need focus on the late stage of retinal dystrophy to test long-term efficacy of the photoelectric dye on overall degeneration of the retinal layers. In addition, it remains unclear how the photoelectric dye prevents photoreceptor degeneration. Further studies are required to elucidate the underlying molecular mechanism of the apoptosis reduction. Semi-quantitative measurements of GFAP and PKC α -immunoreactivity, as a limitation in the method, would explain inconsistent results in statistical analyses of measurements.

【結論】 [Conclusion](#)

our results show that the injection of the photoelectric dye could effectively reduce the apoptosis of photoreceptor cells and downregulate GFAP expression. In the present study, we showed the threshold of the concentration for preventing the photoreceptor degeneration. The best concentration would be obtained from a cell culture experiment at the next step. We confirmed biological safety of the photoelectric dye in all tests, including cell safety test, Ames test, chromosomal aberration test, eye irritation test, skin sensitivity test, acute (a single injection) and subacute (28-day repeated injection) systemic toxicity test (data not shown). The photoelectric dye might be a candidate agent for slowing photoreceptor degeneration. In addition, retinal prosthesis, OUREPTM, would be positioned as a medical device with pharmacological effect to prevent neuronal apoptosis in the retina.
